

OVERFITTING

What is overfitting

Overfitting literally means "Fitting the data more than is warranted." The main case of overfitting is when you pick the hypothesis with lower E_{in} , and it results in higher E_{out} . This means that E_{in} alone is no longer a good guide for learning.

Classic overfitting: simple target with excessively complex H . $E_{in} \approx 0$; $E_{out} \gg 0$

Here is an example of overfitting:

We conclude that:

Number of data points \uparrow	Overfitting \downarrow
Noise \uparrow	Overfitting \uparrow
Target complexity \uparrow	Overfitting \uparrow

Two types of noise

We would like to learn from \circ :

$$y_n = f(x_n)$$

Unfortunately, we only observe \circ :

$$y_n = f(x_n) + \text{'stochastic noise'}$$

no one can model this

We would like to learn from \circ :

$$y_n = h^*(x_n)$$

Unfortunately, we only observe \circ :

$$y_n = f(x_n) = h^*(x_n) + \text{'deterministic noise'}$$

H cannot model this

Stochastic Noise — Data Error

Stochastic Noise: fluctuations/measurement errors we cannot model. Re-measure y_n stochastic noise changes. change H stochastic noise the same.

Deterministic Noise — Model Error

Deterministic Noise: the part of f we cannot model. re-measure y_n deterministic noise the same. change H deterministic noise changes.

Using the bias and variance decomposition view we have:

$$E_D[E_{out}] = \sigma^2 + bias + var$$

The first two terms reflect the direct impact of the stochastic and deterministic noise. The variance of the stochastic noise is σ^2 and the bias is directly related to the deterministic noise in that it captures the model's inability to approximate f . The var term is indirectly impacted by both types of noise, capturing a model's susceptibility to being led astray by the noise.

How to fix it!

Regularization

Using the soft constraint

Don't set weights explicitly to zero (eg $w_3 = 0$). Give a budget and let the learning choose.

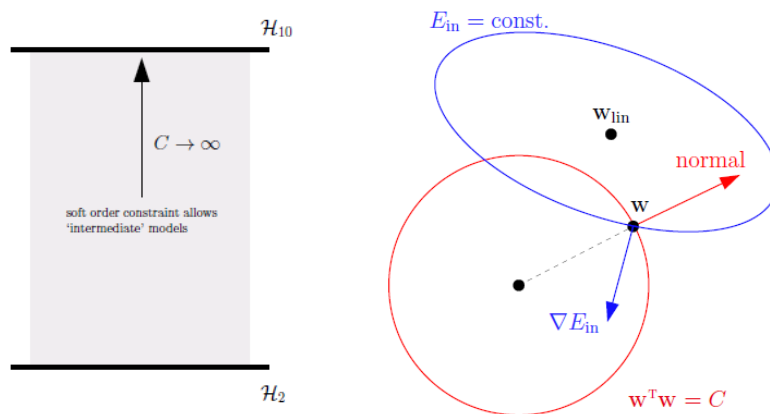

$$\sum_{q=0}^Q w_q^2 \leq C$$

Then w_{reg} is a solution to

$$\begin{aligned} \min : E_{in}(w) &= \frac{1}{N} (Zw - y)^T (Zw - y) \\ \text{subject to : } w^T w &\leq C \end{aligned}$$

Observations:

1. Optimal w tries to get as 'close' to w_{lin} as possible. Optimal w will use full budget and be on the surface $w^T w = C$.
2. Surface $w^T w = C$, at optimal w , should be perpendicular to ∇E_{in} . Otherwise can move along the surface and decrease E_{in} .
3. Normal to surface $w^T w = C$ is the vector w .
4. Surface is $\perp \nabla E_{in}$; surface is \perp normal. ∇E_{in} is parallel to normal (but in opposite direction).

Then problem can be changed to:

$$\min : E_{aug}(w) = E_{in}(w) + \lambda_C w^T w$$

How does regularization work:

Stochastic noise — \rightarrow nothing you can do about that.

Good features — \rightarrow helps to reduce deterministic noise.

Regularization: Helps to combat what noise remains, especially when N is small. Typical modus operandi: sacrifice a little *bias* for a huge improvement in *var*. VC angle: you are using a smaller H without sacrificing too much E_{in}

Uniform Weight Decay

$$\sum_{q=0}^Q w_q^2$$

Low Order Fit

$$\sum_{q=0}^Q q w_q^2$$

Weight Growth!

$$\sum_{q=0}^Q \frac{1}{w_q^2}$$

The first encourages all weights to be small, uniformly; the second pays more attention to the higher order weights, encouraging a lower order fit. In the shaded region, E_{out} increases as you decrease E_{in} (decrease λ) - the regularization parameter is too small and there is not enough of a constraint on the learning, leading to decreased performance because of overfitting. In the unshaded region, the regularization parameter is too large, over-constraining the learning and not giving it enough flexibility to fit the data, leading to decreased performance because of underfitting.

Even though we don't know either the target function or the noise, regularization helps by reducing the impact of the noise. Most common models have hypothesis sets which are naturally parameterized so that smaller parameters lead to smoother hypotheses. Thus, a weight decay type of regularizer constrains the learning towards smoother hypotheses. This helps, because stochastic noise is 'high frequency' (non-smooth). Similarly, deterministic noise (the part of the target function which cannot be modeled) also tends to be non-smooth. Thus, constraining the learning towards smoother hypotheses 'hurts' our ability to overfit the noise more than it hurts our ability to fit the useful information. These are empirical observations, not theoretically justifiable statements.

$$\lambda = 0$$

$$\lambda = 0.0001$$

$$\lambda = 0.01$$

$$\lambda = 1$$

Overfitting

Underfitting

Lasso&Ridge regularization

Introduction

Prior to lasso, the most widely used method for choosing which covariates to include was stepwise selection, which **only improves prediction accuracy in certain cases, such as when only a few covariates have a strong relationship with the outcome**. However, in other cases, it can make prediction error worse. Also, at the time, ridge regression was the most popular technique for improving prediction accuracy. Ridge regression improves prediction error by shrinking large regression coefficients in order to reduce overfitting, but it does not perform covariate selection and therefore does not help to make the model more interpretable.

Lasso is able to achieve both of these goals by forcing the sum of the absolute value of the regression coefficients to be less than a fixed value, which **forces certain coefficients to be set to zero**, effectively choosing a simpler model that does not

include those coefficients. This idea is similar to **ridge regression**, in which the sum of the squares of the **coefficients is forced to be less than a fixed value**, though in the case of ridge regression, this only shrinks the size of the coefficients, **it does not set any of them to zero**.

General form

Lasso regularization can be extended to a wide variety of objective functions such as those for generalized linear models, generalized estimating equations, proportional hazards models, and M-estimators in general, in the obvious way.[1][3] Given the objective function

$$\frac{1}{N} \sum_{i=1}^N f(x_i, y_i, \alpha, \beta)$$

the lasso regularized version of the estimator will be the solution to

$$\min_{\alpha, \beta} \frac{1}{N} \sum_{i=1}^N f(x_i, y_i, \alpha, \beta) \text{ subject to } \|\beta\|_1 \leq t$$

where only β is penalized while α is free to take any allowed value, just as β_0 was not penalized in the basic case.

Consider a sample consisting of N cases, each of which consists of p covariates and a single outcome. Let y_i be the outcome and $x_i := (x_1, x_2, \dots, x_p)^T$ be the covariate vector for the i th case. Then the objective of lasso is to solve. It can be helpful to rewrite

$$\begin{aligned} \min_{\beta \in \mathbb{R}^p} \left\{ \frac{1}{N} \|y - X\beta\|_2^2 \right\} \text{ subject to } \|\beta\|_1 \leq t. \quad \text{Lasso} \\ \min_{\beta \in \mathbb{R}^p} \left\{ \frac{1}{N} \|y - X\beta\|_2^2 \right\} \text{ subject to } \|\beta\|_2 \leq t. \quad \text{Ridge} \end{aligned}$$

in the so-called Lagrangian form

$$\begin{aligned} \min_{\beta \in \mathbb{R}^p} \left\{ \frac{1}{N} \|y - X\beta\|_2^2 + \lambda \|\beta\|_1 \right\} \quad \text{Lasso} \\ \min_{\beta \in \mathbb{R}^p} \left\{ \frac{1}{N} \|y - X\beta\|_2^2 + \lambda \|\beta\|_2 \right\} \quad \text{Ridge} \end{aligned}$$

where the exact relationship between t and λ is data dependent.

Geometric interpretation

As discussed above, lasso can set coefficients to zero, while ridge regression, which appears superficially similar, cannot. This is due to the difference in the shape of the constraint boundaries in the two cases. Both lasso and ridge regression can be interpreted as minimizing the same objective function

$$\min_{\beta_0, \beta} \left\{ \frac{1}{N} \|y - \beta_0 - X\beta\|_2^2 \right\}$$

but with respect to different constraints: $\|\beta\|_1 \leq t$ for lasso and $\|\beta\|_2 \leq t$ for ridge. From the figure, one can see that the constraint region defined by the ℓ^1 norm is a square rotated so that its corners lie on the axes (in general a cross-polytope), while the region defined by the ℓ^2 norm is a circle (in general an n -sphere), which is rotationally invariant and, therefore, has no corners. As seen in the figure, a convex object that lies tangent to the boundary, such as the line shown, is likely to encounter a corner (or in higher dimensions an edge or higher-dimensional equivalent) of a hypercube, for which some components of β are identically zero, while in the case of an n -sphere, the points on the boundary for which some of the components of β are zero are not distinguished from the others and the convex object is no more likely to contact a point at which some components of β are zero than one for which none of them are.

Validation

Validation set

Two goals of validation set:

- The primary goal is to get the best possible hypothesis, so we should output g , the hypothesis trained on the **entire set** V .
- The secondary goal is to estimate E_{out} , which is what validation allows us to do. Based on our discussion of learning curves, $E_{out}(g) \leq E_{out}(g^-)$.

Difference between validation set and test set:

Regularization attempts to minimize E_{out} by working through the equation and concocting a heuristic term that emulates the penalty term. Validation, on the other hand, cuts to the chase and estimates the out-of-sample error directly.

$$E_{out}(g) = E_{in}(g) + \text{overfit penalty} \quad \text{Regularization}$$

VC bounds this using a complexity error bar for H regularization estimates this through a heuristic complexity penalty for g .

$$E_{out}(g) = E_{in}(g) + \text{overfit penalty} \quad \text{Validation}$$

validation estimates this directly

There is a difference between a validation set and a test set. Although the validation set will not be directly used for training, it will be used in making certain choices in the learning process. The minute a set affects the learning process in any way, it is no longer a test set.

Price of validation set

There is a price to be paid for setting aside K data points to get this unbiased estimate of E_{out} : when we set aside more data for validation, there are fewer training data points and so g^- becomes worse; $E_{out}(g^-)$, and hence the expected validation error, increases (the blue curve).

A rule of thumb in practice is to set $K = \frac{N}{5}$ (set aside 20% of the data for validation).

E_{val} is an estimate for $E_{\text{out}}(g^*)$

$$\mathbb{E}_{D_{\text{val}}}[\mathbf{e}_k] = E_{\text{out}}(g^*)$$

$$\begin{aligned}\mathbb{E}[E_{\text{test}}] &= \frac{1}{K} \sum_{k=1}^K \mathbb{E}[\mathbf{e}_k] \\ &= \frac{1}{K} \sum_{k=1}^K E_{\text{out}}(g^*) = E_{\text{out}}(g^*)\end{aligned}$$

$\mathbf{e}_1, \dots, \mathbf{e}_K$ are independent

$$\begin{aligned}\text{Var}[E_{\text{val}}] &= \frac{1}{K^2} \sum_{k=1}^K \text{Var}[\mathbf{e}_k] \\ &= \frac{1}{K} \text{Var}[\mathbf{e}(g^*)]\end{aligned}$$

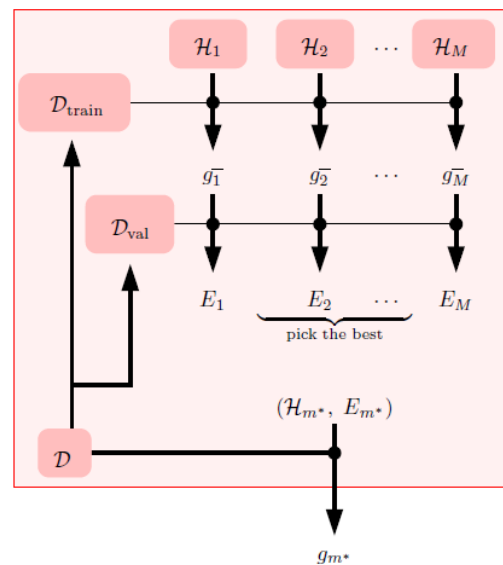

1. Remove K points from \mathcal{D}
 $\mathcal{D} = \mathcal{D}_{\text{train}} \cup \mathcal{D}_{\text{val}}$.
2. Learn using $\mathcal{D}_{\text{train}} \rightarrow g^*$.
3. Test g^* on $\mathcal{D}_{\text{val}} \rightarrow E_{\text{val}}$.
4. Use error E_{val} to estimate $E_{\text{out}}(g^*)$.

Model selection

This could mean the choice between a linear model and a nonlinear model, the choice of the order of polynomial in a model, the choice of the value of a regularization parameter, or any other choice that affects the learning process.

It is now a simple matter to select the model with lowest validation error. Let m^* be the index of the model which achieves the minimum validation error. So for H_{m^*} , $E_{m^*} \leq E_m$ for $m = 1, \dots, M$. The model H_{m^*} is the model selected based on the validation errors. Note that E_{m^*} is no longer an unbiased estimate of $E_{\text{out}}(g_{m^*})$. Since we selected the model with minimum validation error, E_{m^*} will have an optimistic bias. Then we have $E_{\text{out}}(g_{m^*}) \leq E_{\text{val}}(g_{m^*}) + O\left(\sqrt{\frac{\ln M}{K}}\right)$.

Model with best g also has best g (leap of faith) We can find model with best g using validation

Cross validation

$$E_{\text{out}}(g) \approx E_{\text{out}}(g^*) \approx E_{\text{val}}(g^*)$$

Validation relies on the following chain of reasoning: (small K) (large K)

Theorem: E_{cv} is an unbiased estimate of $E_{\text{out}}(N-1)$ (the expectation of the model performance, $E[E_{\text{out}}]$, over data sets of size $N-1$). We have

$$E_{\text{out}}(g^{(N)}) \leq E_{\text{out}}(N-1) \leq E_{\text{cv}} + O\left(\frac{1}{\sqrt{N}}\right)$$

10-Fold cross validations:

Cross validation for selecting $A(\lambda)$:

- 1: Define M models by choosing different values for A in the augmented error: $(H, A_1), (H, A_2), \dots, (H, A_M)$
- 2: for each model $m = 1, \dots, M$ do
- 3: Use the cross validation module in Figure 4.14 to estimate $E_{cv}(m)$, the cross validation error for model m .
- 4: Select the model m^* with minimum $E_{cv}(m^*)$.
- 5: Use model (H, A_{m^*}) and all the data D to obtain the final hypothesis g_{m^*} . Effectively, you have estimated the optimal A .

Conclusion

1. Noise (stochastic or deterministic) affects learning adversely, leading to overfitting.
2. Regularization helps to prevent overfitting by constraining the model, reducing the impact of the noise, while still giving us flexibility to fit the data.
3. Validation and cross validation are useful techniques for estimating E_{out} . One important use of validation is model selection, in particular to estimate the amount of regularization to use.
